INTRODUCTION

Rapid cycling syndrome is a bipolar affective disorder, amounting to 10% to 30% of the bipolar population. It is characterized by at least four episodes per year and rapid shifts between cycles. Patients with bipolar affective disorder, as well as patients with rapid cycling syndrome, typically experience their first major mood episode during adolescence (1–5).

Recently, gene expression data from post mortem brains of bipolar patients were compared with those of healthy controls in two independent studies (6,7). While not disease causing, such gene expression changes in PBMC may shed light on similar cyclic alterations in brain.

To study quantitative peripheral gene expression, we specifically refrained from comparing larger groups of bipolar patients (who are genetically heterogeneous and differ in baseline gene expression profiles), and aimed instead at monitoring the gene expression in one individual, serving always as her own control, at recurrent stages of the disease.

CASE REPORT

The female patient, born in 1945, had no prior medical illness and no evidence of neuropsychiatric illnesses in her family. In 1991, she became ill with rapid cycling syndrome and kept a diary over her illness, used to reconstruct 108 cycles over a 16-year period. The time series suggests...
complex rhythms in periodicity with mean total cycle lengths of $53 \pm 21$ d, switching within hours between manic (mean $28 \pm 14$ d) and depressed (mean $26 \pm 14$ d) episodes without normal intervals (Supplementary Figure 1). Results of affective rating scales obtained repeatedly during depressed and manic episodes, together with psychopathology, neuropsychological test results, appearance, autonomic, and physical signs are summarized in Table 1.

In addition to typical affective symptoms, the patient has physical and cognitive signs recurring in an episode-specific manner. In the first 2 to 3 d of a manic episode, she is sleepless and restless; in the following d, she sleeps 3 to 4 h per night. The 2 to 3 d before the end of manic episodes, she notes a ‘normalization of sleep’ with non-interrupted sleep of regular 8 h duration. The patient eats and drinks excessively during manic episodes, leading to alternating weight changes (up to 5 kg) between episodes and hyperhydration, resulting in significant shifts of hematocrit and hemoglobin concentrations. Three d after the onset of manic episodes, the patient regularly develops

edema in her lower extremities that recover immediately after onset of depression. Only during manic episodes does she become susceptible to seasonal allergies (hay fever). This allergic response is rarely observed during depressed episodes. Witnesses describe a change of her voice in the last 2 to 3 d of manic episodes to raspy and less melodieous. At the end of depressed episodes, her voice becomes more cheerful and richer in tonal inflections. The patient is not aware of these changes. Because there was an episode-specific susceptibility to allergens, lymphocyte subpopulations were studied by fluorescence-activated cell sorting in different episodes. Subtle shifts between CD4-helper and CD8-suppressor cells were noted (Supplementary Figure 2).

The cyclic pattern of the patient’s affective disorder has had a poor response to pharmacologic treatment over the past 16 years, such as lithium, venlafaxine, chlorprothixene, citalopram, paroxetine, carbamazepine, valproic acid, trimipramine, lamotrigine, olanzapine, or flupentixol, and no response to psychotherapy and hypnosis. Antipsychotic medication, such as flupentixol, somewhat reduced the severity of symptoms but not the cyclic behavior of the disorder. During the time of all analyses presented here, the patient was on continuous lamotrigine medication (400 mg), resulting in comparable serum levels of 4.1–8.9 μg/mL upon repeated controls (therapeutic range: 2-10 μg/mL). No other medication was allowed 2 wks before or during the time of each testing, or before and during the treatment approach, reported here, using the cycloxygenase inhibitor celecoxib (Celebrex, Pfizer, Karlsruhe, Germany, 2 x 200 mg daily per os).

MATERIALS AND METHODS

Strategy of Episode-Dependent Gene Shift Detection

A three-tiered approach was used to identify candidate genes that are expressed in an episode-specific fashion. In the first step, eight blood samples for PBMC isolation (see below) were collected (always at 8:00 a.m. after overnight fasting conditions) in the approximate middle of two different consecutive depressed and manic episodes on two consecutive days each. All sample collection was done well outside the hay fever season and in complete absence of allergic symptoms. The screening identified genes that showed at least two-fold differences in expression in manic compared with depressed episodes, and vice versa. After screening by microarrays, the data set was submitted to two bioinformatic processing steps (see below). The data were normalized and analyzed to identify and exclude genes that differed between the two consecutive days within a particular episode (arbitrary daily variation). Further genes were excluded that were differentially expressed within the two depressed or within the two manic episodes (arbitrary monthly variation). The expression pattern of the remaining depressed and manic episode genes was subsequently compared. Using this approach, several genes were identified that showed high expression in depressed and low in manic episodes, and vice versa. Because the patient never had periods where she was free of symptoms, samples could not be obtained within an euthymic episode.

Isolation of Peripheral Blood Mononuclear Cells (PBMC)

PBMC were collected applying the standard Ficoll-Paque Plus isolation procedure (Amersham Biosciences, Freiburg, Germany). RNA was prepared using Trizol and Qiagen RNAeasy columns (Qiagen, Hilden, Germany). The RNA samples were used to synthesize cDNAs (SuperScriptIII, Invitrogen, Karlsruhe, Germany).

DNA Microarray Analysis

Transcriptome analysis was performed using the GeneChip Human Genome U133 Plus 2.0 (Affymetrix, Santa Clara, CA, USA) (8) according to the published protocols (9). All cDNAs used for microarrays were one-round amplified. GeneChip data were analyzed using the software GCOS version 1.2 (Affymetrix). Detailed data analysis was performed with R open-source software, and the open-source Bioconductor platform.

Quantitative Real-Time Reverse Transcriptase Polymerase Chain Reaction (qRT-PCR)

Genes found to be differentially regulated by DNA microarray analysis were subsequently validated independently using qRT-PCR. Cyclic changes in the expression of these genes were confirmed further on PBMC of additional blood samples obtained up to two years after the initial screen. qRT-PCR was performed with the aid of SYBR Green detection on Applied Biosystems 7500 Fast System. CT (cycle threshold) values were standardized to CT values of GAPDH. Primers are listed in Supplementary Table 1.

Statistical Analyses

All numerical results are presented as mean ± SD in the text and mean ± SEM in the Figures. Statistical analyses (10,11) and Fast Fourier Transformations (12) were performed as published using MATLAB R2007a software. Nonparametric independent Mann-Whitney U test (two-tailed) and Student t test (two-tailed) were calculated using SPSS 16.0 for Windows.

All supplementary materials are available online at molmed.org.

RESULTS

A three-tiered approach was employed to identify genes that were regulated in an episode-specific fashion (Figure 1A). We grouped the genes in biological categories and present their mean expression pattern over six to ten separate time points during either depression or mania (Figure 1B–1E).

Notably, the genes involved in prostaglandin metabolism, PTGDS (lipocalin-type prostaglandin D synthetase), and AKR1C3 (prostaglandin D2
11-ketoreductase), showed higher expression in depressed episodes (Figure 1B). We also identified two neurodevelopmental genes that revealed opposing gene expression: NRG1 (neuregulin-1) was expressed higher in manic, SPON2 (spandin-2) in depressed episodes (Figure 1C). Several other genes, involved in regulation of the immune system, were episode-specifically expressed. These include GZMA (granzyme A) and KLRD1 (killer cell lectin-like receptor subfamily D, member 1/CD94) with higher expression in depressed as compared with manic episodes (Figure 1D). Hemoglobin genes A and B (HBB and HBA) were higher in manic, compared with depressed episodes. This contrasts the hemoglobin (protein) concentration in whole blood (insert) showing opposite regulation (Figure 1E).

As discussed below, the most intriguing finding was the association of prostaglandin-synthesizing genes PTGDS (lipocalin-type prostaglandin D synthetase) and AKR1C3 (prostaglandin D2 11-ketoreductase) with rapid cycling. We undertook a clinical experiment to explore the relevance of this observation and to distinguish between a disease marker and mediator. We offered to the patient a treatment approach applying (off-label) the cyclooxygenase inhibitor celecoxib (Celebrex, Pfizer, 2 × 200 mg daily oral).

Treatment with celecoxib was started with 100 mg and increased by 100 mg daily to reach the final dose of 400 mg (2 × 200 mg daily) at d 4. This dose has been continued for more than 5 months and is well tolerated. Figure 2 illustrates the clinical course before and during celecoxib, including psychopathology ratings that revealed a significant improvement of depressed as well as of manic symptoms.

**DISCUSSION**

In our first molecular-genetic approach to alternating gene expression in bipolar disorders, we used PBMC of a woman with 16-year history of an extreme form of rapid cycling, and obtained an episode-specific gene expression pro-
GENE EXPRESSION IN RAPID CYCLING SYNDROME

file on an identical genetic background. Our strategy was set up to minimize the risk of identifying false positive genes, due to daily or monthly variations in gene expression that are disorder-unrelated. The gene expression differences among episodes are small but significant, and would not have been recognized in a pool of patients or in comparison with healthy controls, due to different genetic background and modifiers of gene expression. In principle, such an approach could be employed as a screening strategy for genes in any condition with temporal periodic behavior, such as sleep or seasonal phenomena/disorders.

Follow-up studies on larger numbers of bipolar patients will have to follow, to confirm the general disease-relevance of the identified gene expression shifts. Specifically, patients with a more typical age of onset and course of bipolar disease will have to be screened. An age of onset of 46 years and cycling over decades without euthymic episodes, as in our patient, clearly is an exception (3–5).

The patient’s impairments comprise psychopathological symptoms in combination with physical signs and symptoms, including the immune system, and a variety of cognitive domains evident upon neuropsychological testing. Accordingly, episode-specific gene expression involved different biological systems, such as blood, metabolism, immune functions, as well as neuronal genes, confirming rapid cycling as a systemic disorder. Like all association studies, we can make no claim whether or not a particular gene expression shift is a cause or consequence of rapid cycling, and whether similar gene expression changes occur in the brain. Moreover, it is currently unknown whether some of the observed alterations in gene expression partly reflect the shifts in immune cell subsets observed here.

Lamotrigine has been shown to alter expression of certain genes, such as GABA-A receptor β3 subunit in rat hippocampal cells (13). During the entire observation period (analysis and experimental treatment) reported in this paper, however, the patient was always on the same dose of lamotrigine (episode-independent), making an influence of this pharmacological treatment on the alternating gene expression shown here very unlikely. No other medication was used.

Some regulated genes identified in PBMC are known to be expressed in the nervous system. For example, NRG1 is a neuronal growth factor regulating differentiation, synaptogenesis, and myelination of the nervous system (14). NRG1 also is expressed in activated monocytes (15). Similarly, SPON2 (spondin, mindin) originally was characterized in zebrafish as a protein in outgrowth of hippocampal

Figure 2. Clinical course of psychopathology ratings before and during treatment with the cyclooxygenase inhibitor celecoxib. The course of the Hamilton Depression Rating Scale (HAM-D) scores, the Young Mania Rating Scale (YMRS) scores, and the Positive and Negative Syndrome Scale (PANSS) scores, presented in line graphs, show a pronounced cycling pattern. Day 0 denotes start of celecoxib intake. The magnitude of cyclic changes appears to gradually decrease during treatment. Bar graphs give scores (mean ± SEM) of n = 6 depressed and n = 6 manic episodes (two before and four after onset of treatment each). HAM-D score in depressed and YMRS score in manic episodes decrease significantly upon treatment. Mean values are compared using independent Student t test (two-tailed). M = manic episode, D = depressed episode.
neurons (16). It is expressed abundantly in lymphoid tissue and involved in inflammation (17).

Granzymes A and B (GZMA and GZMB) and several natural killer cell receptors were higher in depressed episodes. We speculate that the observed episode-specific gene expression contributes to the pathogenesis seen in our patient, including her allergic diathesis. In contrast, the elevated globin gene expression in manic episodes found here may reflect a physiological counter-regulation to the relative increase in extracellular fluid (and decrease in hemoglobin level) due to massive drinking.

Interestingly, two genes were identified that are essential for prostaglandin synthesis, PTGDS and AKR1C3. PTGDS marks the hibernation cycle, and accumulation of prostaglandins during hibernation season has been described in hibernating animals (18,22). Based on our molecular data, we speculate that the rapid cycling syndrome in humans may reflect an evolutionary ancient behavioral program resembling the hibernation cycle (with periodic eating, high psychomotor activity and nesting behavior, alternating with episodes of rest and sleep) (41,42) that becomes pathologically re-activated by unknown triggers, thereby creating rapid cycling.

The gene products involved in prostaglandin metabolism might give clues to potential treatment targets, but to confirm their general relevance in bipolar disease, more patients will have to be examined for cycling-associated alterations in prostaglandin gene expression. Nevertheless, the positive result of the clinical experiment with celecoxib in our patient, showing considerable attenuation of both depressed and manic rating scores, supports a mediator role of prostaglandins in rapid cycling. We are fully aware of the limitation of a case report in comparison to a clinical trial. However, we note that the 16-year clinical history of our patient has never shown benefits from any of the many pharmacological treatments, suggesting that a potential placebo effect in our experiment would be minor.

Supporting our findings, a recent proof-of-concept trial in Germany including patients with major monopolar depression found beneficial effects on mood upon 6-wk add-on treatment with the cyclooxygenase-2 inhibitor celecoxib. In contrast to our gene expression-based “hibernation hypothesis of bipolar disease,” this trial was based on the hypothesis that inflammatory processes might be involved in the pathogenesis of depression (43). Following the same inflammation hypothesis of depression, another small 6-wk study was performed in the United States of America, exploring the effect of celecoxib as adjunctive agent in bipolar depression, also with promising results (44). Bringing hibernation and inflammation together, it is intriguing to speculate that rapid cycling bipolar disorders are characterized by episodic self-limiting inflammatory processes that, unlike other inflammatory conditions in the brain, do not lead to overt neurodegeneration.

ACKNOWLEDGMENTS

The study was supported by the Max Planck Society, by several private donations, as well as by the DFG Center for Molecular Physiology of the Brain (CMPB). The authors would like to thank Jeannine Dietrich and Kathrin Hannke for excellent assistance and Fred Wolf for helpful discussions.
